HYPOXIA AND INNATE IMMUNITY
Adapting to low oxygen levels

Rho family GTPases
Integrating signals for lymphocyte development and activation
Acute foci of tissue inflammation, whether generated in response to infection, injury, noxious agents or autoimmunity, present a unique and challenging microenvironment. Hypoxia (low oxygen) or anoxia (complete lack of oxygen), hypoglycaemia (low blood glucose), acidosis (high H⁺ concentration) and abundant free oxygen radicals are characteristic features of inflamed tissues, along with the influx of specialized myeloid cells such as neutrophils and macrophages. In healthy tissues the oxygen tension is generally 20–70 mm Hg (that is, 2.5–9% oxygen), whereas markedly lower levels (<1% oxygen) have been described in wounds and necrotic tissue sites. The extreme local hypoxia is a consequence of decreased perfusion, which is secondary to microvascular injury, thrombosis or increased interstitial pressure, coupled with the metabolic activities of the infectious pathogen and the recruited inflammatory cells.

Myeloid cells are short-lived cells that are rapidly mobilized in response to any change in tissue integrity or entry of pathogenic microorganisms. They carry out phagocytosis of invading microorganisms and tissue debris and release a diverse array of antimicrobial molecules and pro-inflammatory mediators. Neutrophils and macrophages are crucial components of innate immune defence, serving to localize and eradicate pathogens and prevent the systemic spread of infection. In particular, neutrophil priming and apoptosis are crucial to the onset and resolution of granulocytic inflammation.

Deficiencies in the numbers of these specialized phagocytic cells (for example, following cancer chemotherapy) or inherited defects in their core effector functions (for example, in chronic granulomatous disease) greatly increase susceptibility to recurrent or severe infections. The intricate regulation of the microbicidal and inflammatory functions of neutrophils and macrophages is central to our understanding of mammalian innate immunity. Innate immune cells must remain quiescent under normal conditions to avoid unwanted inflammatory injury to host tissues, but be capable of instantaneous activation when recruited to sites of infection. Extensive investigations have defined cell surface receptors and downstream signalling pathways that allow these cells to rapidly activate gene transcription and to release preformed antimicrobial effectors following recognition of pathogens or cytokines. The field is gaining an improved understanding of how another key feature of the inflammatory tissue microenvironment, the scarcity of oxygen, influences the terms of engagement between phagocytic cells and pathogens. In this Review, we describe how these front line innate immune effector cells have evolved to generate energy and carry out their microbicidal functions under hypoxic conditions. From these fundamental functions emerges an interdependence of the innate immune response and the hypoxic response, revealing a central role for the hypoxia-inducible factors (HIFs) as regulators of mammalian innate defence.

**Interdependence of hypoxic and innate immune responses**

*Victor Nizet* and Randall S. Johnson

Abstract | Hypoxia-inducible factor (HIF) is an important transcriptional regulator of cell metabolism and the adaptation to cellular stress caused by oxygen deficiency (hypoxia). Phagocytic cells have an essential role in innate immune defence against pathogens and this is a battle that takes place mainly in the hypoxic microenvironments of infected tissues. It has now become clear that HIF promotes the bactericidal activities of phagocytic cells and supports the innate immune functions of dendritic cells, mast cells and epithelial cells. In response to microbial pathogens, HIF expression is upregulated through pathways involving the key immune response regulator nuclear factor-κB, highlighting an interdependence of the innate immune and hypoxic responses to infection and tissue damage. In turn, HIF-driven innate immune responses have important consequences for both the pathogen and the host, such that the tissue microenvironment fundamentally influences susceptibility to infectious disease.

**HIF: a central regulator of the hypoxic response**

The HIF protein complex was originally discovered through its contribution to the marked induction of erythropoietin (EPO) gene transcription under hypoxic conditions. Further characterization showed that HIF is a heterodimeric helix-loop-helix transcription factor, the expression of which is regulated by both oxygen and iron (Fig. 1). HIF is active in all mammalian cells and is now known to regulate the expression of more than 100 genes that function in various host cellular and systemic responses to stress triggered by low oxygen levels. HIF-controlled pathways influence metabolism, angiogenesis, vascular tone, cell differentiation and apoptosis, and have implications for normal physiology and development but also for cancer and many other pathological conditions.

**a** O₂ abundant: normoxia

The HIF DNA-binding complex is comprised of the constitutively expressed HIF1β (also known as ARNT) subunit, which partners with one of two hypoxia-inducible α-subunits, HIF1α or HIF2α (also known as EPAS1). The HIF α-subunits are unstable under normoxic conditions as cells continually synthesize and degrade them. The half-lives of HIF1α and HIF2α are short owing to the activities of a family of oxygen- and iron-dependent prolyl hydroxylases (PHD1, PHD2 and PHD3), the actions of which direct HIF α-subunits for degradation by the ubiquitin–proteasome pathway in a process that depends on interaction with von Hippel–Lindau tumour suppressor protein (VHL). A further level of control is provided by another hydroxylase, the asparaginyl hydroxylase factor inhibiting HIF (FIH; also known as HIF1AN), which has been shown to function in conjunction with the prolyl hydroxylation, although in this case to hydroxylate an asparagine residue in the carboxy-terminal domain of HIF1α. This blocks the association of HIF1α with p300–CBP, which in turn inhibits transcriptional enhancement by the HIF complex (not shown). As all of these post-translational events depend on intracellular oxygen they are inhibited by oxygen deprivation.

**b** O₂ scarce: hypoxia

Under hypoxic conditions, HIF1α gene expression is upregulated through nuclear factor-κB (NF-κB) activation downstream of Toll-like receptors (TLRs), and the unmodified form of HIF1α in association with p300–CBP migrates to the nucleus to bind HIF1β (also known as ARNT), forming a heterodimeric helix-loop-helix transcriptional regulator. The HIF complex binds to target promoters known as hypoxic-response elements (HREs), leading to the transcription of genes that promote macrophage and neutrophil energy generation, inflammatory and bactericidal activities, and survival. Ub, ubiquitin.

Activation of most cathelicidin precursors requires proteolytic cleavage to release the C-terminal domain, which has microbicidal and immunomodulatory activities.

HIF function in myeloid cells

HIF control of myeloid cell inflammatory activities. Indicative of the central roles of HIF1α in development and physiology, deletion of HIF1α in mice results in lethal embryonic defects in vascular development and morphology14–19. Recently, a conditional gene targeting strategy exploiting Cre–LoxP recombination was used for lineage-specific elimination of HIF1α in macrophages and neutrophils. A mouse line was engineered to contain LoxP sites flanking the Hif1a gene, and these mice were then crossed with mice in which the myeloid cell-specific lysozyme M promoter drives Cre recombinase expression. The resultant mice, which showed markedly decreased HIF1α expression levels specifically in myeloid cells, have no obvious phenotypic abnormalities under normal conditions but showed marked aberrations in experimental models of acute inflammation20. In contrast to their wild-type littermates, mice with a myeloid cell Hif1a conditional deletion did not develop severe joint swelling and cartilage destruction in a collagen-induced arthritis model and showed no cutaneous redness or oedema following application of a chemical irritant to the skin, indicating impaired inflammatory responses21. The HIF1α-deficient macrophages and neutrophils had lower levels of cellular ATP (15–40% of wild-type levels), highlighting the crucial role of the transcription factor for energy generation through glycolysis in these immune cells22. Evidence of HIF activation in the diseased tissues of patients with inflammatory disorders, such as rheumatoid arthritis21,22, dermatomyositis23, neonatal lupus syndrome24 and atherosclerosis25, suggests an important role for the hypoxic response in various human immunopathologies.

HIF control of myeloid cell defence functions. Neutrophils and macrophages are not only participants in acute and chronic inflammatory pathologies but also crucial front line effectors of innate host defence against invading microbial pathogens. Although the oxygen percentage in healthy tissues ranges from 2.5–9% oxygen, markedly lower levels (<1% oxygen) are characteristic of wounds and sites of infection (Box 1). Thus, phagocytic cells must be adapted to generate energy and function effectively in oxygen-deprived conditions, especially as many common bacterial pathogens proliferate readily in anaerobic microenvironments. Analysis of the bactericidal capacities of phagocytes from Hif1a conditional knockout mice confirmed a pivotal role for the hypoxic response in innate host defence. Macrophages isolated from mice deficient in HIF1α are impaired in their capacity to kill Gram-positive and Gram-negative bacteria compared with wild-type macrophages22,26. When challenged subcutaneously with group A streptococcus, mice with a myeloid cell Hif1a conditional deletion developed significantly larger necrotic ulcers and had higher bacterial loads in the infected tissue and blood26.

Analysis of the host–pathogen encounter by multiple cell groups has revealed several aspects of myeloid cell function that depend on HIF. In neutrophils, HIF induces β2 integrin expression and thereby promotes neutrophil binding to the epithelium27. HIF increases neutrophil expression of antimicrobial molecules such as cathelicidin peptides and the granule proteases cathepsin G and elastase26. HIF also extends the lifespan of functional neutrophils by inhibiting apoptotic pathways28–30. Increased levels of HIF are also evident during the differentiation of blood monocytes into tissue macrophages31. HIF activity has been described as a key aspect of phagocytic uptake of bacteria by macrophages under hypoxic conditions31, and macrophage production of tumour necrosis factor (TNF) and synthesis of nitric oxide (NO) through inducible NO synthase (iNOS) is HIF dependent32. HIF-responsive elements are also found in the genes encoding Toll-like receptors (TLRs), including TLR2 and TLR6, which are upregulated in response to hypoxia32. Finally, HIF markedly increases the release of pro-inflammatory cytokines and the expression of co-stimulatory molecules by murine dendritic cells (DCs), enhancing their ability to induce allogeneic lymphocyte proliferation and therefore helping to bridge innate and adaptive immune responses33.

Box 1 | Defining oxygenation states

Normoxia
Generally defined as either atmospheric oxygen at sea level for tissue culture or as physiological oxygenation in a well-vascularized and perfused tissue. Oxygenation of tissues depends on the tissue in question, and in the case of innate immune cells it becomes an even more elusive quantity to define.

Hypoxia
In tissue culture, hypoxia is generally defined as levels that are equivalent to between 0.5% and 3% oxygen by volume in the air that perfuses the growth medium. For actual tissues in vivo hypoxia is more difficult to define but is generally thought to occur in any tissue where injury or another alteration in perfusion causes a significant reduction in tissue oxygen levels relative to those that exist normally. Functionally, hypoxia exists in vivo whenever oxygen demand exceeds oxygen supply.

Anoxia
Defined in both tissue culture and physiology as the absence of physiologically available oxygen. Anoxia can occur in tissues in areas of acute infection or severe damage.
One notable exception to the HIF-mediated regulation of phagocyte function may be the generation of superoxides by the oxidative burst, which seems to occur with equal efficiency in wild-type and HIF1α-deficient macrophages.

**Synergism of the hypoxic and innate immune responses.**
A surprising consequence of the findings summarized above is that, because of HIF activation, myeloid cells phagocytose and kill bacteria better under hypoxic conditions than they do under normoxic conditions. Strikingly, bacteria are an even stronger stimulus for HIF protein stabilization than is hypoxia itself, and bacteria-induced HIF protein stabilization can be readily shown under normoxia. Recently, the mechanistic explanation for these phenomena has been found to reflect a close, synergistic relationship between HIF and a central regulator of innate immunity, nuclear factor-kB (NF-kB) (a transcription factor).

NF-kB activity is controlled by inhibitor of NF-kB (IkBs), mainly IKKβ, which carry out the phosphorylation-dependent degradation of IkB inhibitors in response to infectious or inflammatory stimuli. HIF was shown to mediate NF-kB activation in neutrophils under anoxic conditions and to promote the expression of NF-kB-regulated cytokines in macrophages stimulated by lipopolysaccharide (LPS) in a TLR4-dependent manner. Interestingly, hypoxia itself can stimulate NF-kB activation by inhibiting prolyl hydroxylases that negatively modulate IKKβ catalytic activity.

NF-kB was found to contribute to increased Hif1a mRNA transcription under hypoxic conditions. The activation of Hif1a transcription by bacteria or LPS under normoxic as well as hypoxic conditions has been recently verified in a study using mice deficient in IKKβ. Macrophages infected with Gram-positive or Gram-negative bacteria, and mice subjected to hypoxia, reveal a marked defect in Hif1a expression following deletion of the gene encoding IKKβ. These results confirm that transcriptional activation of Hif1a by IKKβ-responsive NF-kB is a crucial precursor to post-transcriptional stabilization and accumulation of HIF1α protein.

Because circulating phagocytes have a unique immune defence function and must transit through different microenvironments during rapid mobilization to infected tissues, the synergistic HIF–NF-kB pathway represents an elegant control mechanism for the specialized activities of these cells. Phagocyte bactericidal

---

**Figure 2 | HIF regulation of phagocyte innate immune functions.** Myeloid-derived phagocytes such as neutrophils and macrophages have low levels of hypoxia-inducible factor (HIF) under normal conditions as they circulate in the oxygen-rich blood. When recruited to tissue sites of infection, they migrate across the endothelium and immediately encounter a decreasing oxygen gradient, which leads to decreased prolyl hydroxylase activity and increased stabilization of HIF1α protein. HIF1α translocates to the nucleus and forms a functional heterodimeric transcription factor with HIF1β (also known as ARNT) (not shown). Expression of innate immune response genes that contain hypoxic-response elements (HREs) in their promoters is increased, but maximal activation occurs only through toll-like receptors (TLRs) and nuclear factor-kB (NF-kB) activation following pathogen encounter, which functions to boost HIF1A transcription. HIF activity promotes phagocytosis; inhibits apoptosis to increase phagocyte lifespan; stimulates the release of antimicrobial peptides, granule proteases, vascular endothelial growth factor (VEGF, which increases vascular permeability) and pro-inflammatory cytokines (such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-12); upregulates TLR expression; and activates the production of nitric oxide by inducible nitric oxide synthase.
and pro-inflammatory capacities can be maintained in an ‘off’ state while the myeloid cells circulate in the oxygen-rich blood, but can then be activated in response to the decreasing oxygen gradient that is encountered following endothelial transcytosis and entry into the infected tissues. The primed phagocyte then undergoes a more potent stimulation of the HIF pathway on direct pathogen encounter and, through recognition of pathogen-associated molecular patterns by TLRs, activation of NF-κB and upregulation of Hif1α mRNA. The maximal ‘on state’ of bactericidal capacities is enhanced by the release of pro-inflammatory cytokines and upregulation of TLR expression. This elegant control system links HIF to the myeloid cell response, ensuring that pro-inflammatory mediators, degradative enzymes and antimicrobial peptides are expressed preferentially at sites of infection, but not in healthy tissues where they would cause unwanted damage to host cells.

So far, functional studies of the HIF–NF-κB pathway in myeloid cell innate immune functions have centred on the role of the HIF1α subunit, but it will be important to expand these analyses to investigate the potential synergistic or modulatory roles of the HIF2α subunit in this context. Periods of prolonged exposure to hypoxic conditions (18 hours) affect the expression of many macrophage cytokines and receptors, including interleukin-1β (IL-1β), IL-8, VEGF, angiopoietin and CX-C chemokine receptor 4 (CXCR4) in both mouse and human macrophages. In addition, recent studies using RNA interference and pharmacological inhibitors suggest that HIF1α and HIF2α, more so than NF-κB, are important in orchestrating the changes in macrophage receptor and cytokine gene expression40. Additional evidence suggests that HIF1α, but not HIF2α, underpins the synergistic induction of iNOS expression and other HRE-dependent transcriptional activities in macrophages following exposure to LPS and hypoxia41.

Role of HIF in other cell types

Evidence is mounting showing that HIF is a key regulator of the intrinsic immune and inflammatory responses in various non-myeloid cell types, including tissue epithelial cells and other specialized leukocytes. For example, the skin provides a highly effective physical, cellular and chemical barrier against microbial penetration42. In response to bacterial pathogens, keratinocytes produce peptides of the cathelicidin and β-defensin family that can directly kill microbial pathogens43. HIF expression is upregulated in the gut epithelium during ischaemia–reperfusion injury44. Specific RNA interference studies confirmed that HIF1α-mediated regulation of keratinocyte cathelicidin production is crucial for cutaneous defence against infection with this invasive pathogen44.

HIF expression is upregulated in the gut epithelium during ischaemia–reperfusion injury, and the level of HIF activation during the reperfusion phase is strongly increased by exposure to LPS or the bacterium Pseudomonas aeruginosa46. Targeted manipulation of HIF1α expression in colonic epithelium also suggests potential roles for HIF1α in the regulation of intestinal mucosal inflammatory responses, although the directionality of the effects has been conflicting. In one study47, mice with intestine-specific disruption of HIF1α expression were protected against dextran sulphate sodium-induced colitis, whereas those with constitutive HIF expression (as a result of VHL deletion) had increased expression of pro-inflammatory mediators, including macrophage migration inhibitory factor (MIF), leading to markedly increased oedema and cellular infiltrates. However, several other studies using different mouse colitis models indicated the opposite: a protective effect of HIF against colonic inflammation following genetic manipulation48 or pharmacological interventions49.

Mast cells are specialized granulocytic cells that are resident in the skin and the mucosa of the respiratory and gastrointestinal tracts. Their roles in allergy are well studied and they are increasingly recognized to function in both innate and adaptive immune responses50. Activation of HIF in human mast cells leads to release of pro-inflammatory cytokines such as IL-8 and TNF51. HIF activation in mast cells of the bronchial epithelium stimulates VEGF expression, leading to increased vascular permeability, protein extravasation into the alveolar space and airway oedema52. Moreover, HIF activation stimulates histidine decarboxylase expression by human mast cells, catalysing the formation of histamine, a potent inflammatory mediator53. To date, the role of HIF in eosinophil inflammatory functions has not been examined directly.

HIF inflammatory responses during sepsis

Sepsis, the leading cause of death in intensive care units, is an aberrant and potentially lethal host response to overwhelming infection, in which bacteria or LPS provoke uncontrolled release of pro-inflammatory cytokines from immune cells, including monocytes and macrophages. LPS raises HIF levels in macrophages through activities of the mitogen-activated protein kinase (MAPK) and NF-κB signal transduction pathways37,39, leading to increased levels of Hif1α mRNA transcripts, which are accompanied by a TLR4-dependent decrease in the levels of mRNAs encoding prolyl hydroxylases35. Studies of LPS challenge of mice with Hif1α-deficient myeloid cells identified HIF as a crucial determinant of the sepsis phenotype, promoting high-level release of the pro-inflammatory cytokines TNF, IL-1 and IL-12. As a consequence, Hif1α deletion in the macrophage lineage protects animals against LPS-induced mortality and blocks the clinical manifestations of sepsis, including hypotension, tachycardia and hypothermia54.

HIF transcriptional regulation also modulates pro-inflammatory cytokine production by CD4+ and CD8+ T cells but, in contrast to findings in myeloid cells, epithelial cells and mast cells, the net effect of T cell-produced HIF might be inhibitory. For example, following T cell receptor activation, the release of TNF and interferon-γ (IFNγ) by T cells with targeted deletion of Hif1α was higher than release by wild-type T cells46. The activated HIF-deficient T cells showed enhanced proliferation.
Caecal ligation and puncture
An experimental model of peritonitis in rodents, in which the caecum is ligated and then punctured. This leads to leakage of intestinal bacteria into the peritoneal cavity and subsequent peritoneal infection.

HIF dynamics in response to infectious pathogens
Viruses. Acute infection with viruses is generally found to induce HIF protein stabilization in target cells (TABLE 1), thus provoking local inflammation. For example, the common respiratory syncytial virus (RSV) induces HIF expression by human bronchial epithelial cells through a NO-dependent pathway, stimulating VEGF production and the airway oedema that is characteristic of acute RSV infection. In some cases, the HIF-dependent innate immune response to viral infection may help to mitigate cytolytic injury and viral replication. Vesicular stomatitis virus (VSV) infection is an acute illness resulting in mouth ulcers in cattle and occasionally in humans. HIF activation by hypoxia or pharmacological agents can increase the expression of IFNβ and other antiviral genes and promote cellular resistance to VSV infection.

By contrast, with certain persistent viral infections the induction of HIF fails to result in eradication of the virus. An unfortunate consequence of HIF activation in these circumstances is that increased VEGF and the accompanying pro-angiogenic programme can contribute to oncogenic transformation. This seems to be the case in chronic infections with the hepatitis B and C viruses (HBV and HCV), which are epidemiologically associated with the development of hepatocellular carcinoma, a highly vascularized solid tumour. Experimental evidence of this includes the finding that HIF levels are increased in liver cells transfected with the oncogenic X protein of HBV (HBx) and in the livers of HBx-transgenic mice. HBx interacts directly with HIF1α to block its association with VHL and degradation by the ubiquitin–proteasome pathway. Recently, HCV infection has also been found to stabilize HIF1α protein, with the involvement of the NF-κB and MAPK signalling pathways, stimulating VEGF production and neovascularization.

Human papilloma virus type 16 (HPV-16) is an aetiological agent of cervical interstitial neoplasia that, if untreated, can progress to cervical carcinoma. Transfection of human cervical cells with the HPV-16 oncoproteins E6 and E7 induces VEGF expression and capillary formation in a HIF-dependent manner, and HPV-16 and HIF1α act synergistically to promote cancer lesions when expressed transgenically in the cervical epithelium of mice. Increased HIF levels

are correlated with poor prognosis of patients with advanced cervical cancer lesions, many of which are demonstrably hypoxic45. HIF activation is also apparent during chronic infection with other viruses that are associated with the risk of neoplastic transformation, including human T cell leukaemia virus type I46 and Epstein–Barr virus47,48. Crosstalk between viral genes and HIF activation has recently been shown to have an intriguing role in regulating the latency and reactivation of human herpesvirus 8 (HHV8). HHV8 infection is associated with the endothelial tumour Kaposi’s sarcoma in patients with AIDS. Biopsies of Kaposi’s sarcoma lesions show high levels of HIF, and HHV8 infection of endothelial cells can stabilize HIF1α subunits and increase HIF target gene expression49. The HHV8 latency-associated nuclear antigen stimulates Hif1a mRNA transcription and also physically interacts with the HIF heterodimer to enhance its promoter-binding activities50. Induction and co-activation during HHV8 infection allow HIF to bind HREs in the viral genome itself; these include one in the promoter of the gene encoding Rta, a key protein involved in reactivation of the virus from latency to a lytic replication phase51.

**Bacteria.** Increased levels of HIF are observed in macrophages and neutrophils stimulated by various bacterial species, including group A and B streptococci, Staphylococcus aureus, Salmonella typhimurium and P. aeruginosa52–54, indicating that HIF responds in a general manner to bacterial infection (TABLE 1). The myeloid cell HIF response pathway is beneficial to innate immune defence, promoting bacterial killing in vitro55,56 and restricting the spread of infection in vivo57. Bacterial products such as LPS and peptidoglycan can activate TLRs and NF-κB signalling to increase the transcription of Hif1α58. Post-translational HIF1α protein stabilization is provided by the exhaustion of oxygen at the tissue site of infection and, perhaps in certain cases, through iron sequestration by bacterial siderophores. Indeed, siderophore-deficient *Versinia enterocolitica* fails to induce HIF activation in intestinal Peyer’s patches59 and the virulence of *Y. enterocolitica* is increased in mice that lack intestinal HIF1α expression, suggesting that the HIF response is important for mucosal innate defence.

* Bartonella henselae* is a facultative intracellular bacterium that causes an angioproliferative disorder known as bacillary angiomatosis in immunocompromised patients. Bacillary angiomatosis lesions show high levels of HIF expression, and *B. henselae* activation of HIF-induced VEGF release is likely to provoke a pro-angiogenic programme that contributes to the characteristic tissue pathology60. Another intracellular bacterial pathogen, *Chlamydia pneumoniae*, has evolved a mechanism to counteract HIF protein stabilization, thereby inhibiting innate immune activation and promoting its survival in host cells. Secretion of a chlamydial protease-like activity factor into the cytoplasm degrades accumulated HIF1α, facilitating continued *C. pneumoniae* replication during hypoxia61.

**Parasites.** Toxoplasma gondii is an obligate intracellular parasite that produces opportunistic infections in fetuses and in immunocompromised individuals. It rapidly induces HIF expression by infected fibroblasts62, which leads to upregulation of genes encoding glycolytic enzymes, glucose transporters and VEGF63. Under hypoxic conditions in the tissues (brain, muscle and retina) in which the parasite produces serious clinical pathology, *T. gondii* replication and organelle maintenance were severely impaired in host cells that lacked HIF1α. It is thought that *T. gondii* has evolved to induce HIF expression because a particular HIF target gene is essential to parasite growth or because HIF activation is necessary to preserve the health of the host cell in which the parasite has become established64. Cutaneous lesions can be generated in BALB/c mice by infection with *Leishmania amazonensis*, and in the later stages of infection HIF is induced in the cytoplasm and parasitophorous vacuoles of macrophages recruited to the skin lesions65. Whether this observed HIF induction contributes to immune resolution of leishmanial infection is not yet understood.

**HIF and SLC11A1 allele expression phenotypes.** Solute-carrier family 11, member A1 (SLC11A1; also known as NRAMP1) is a proton-coupled divalent ion transporter that is involved in iron metabolism, resistance to pathogens and inflammatory responses. SLC11A1 was the first infectious disease susceptibility gene to be identified by positional cloning, and allelic variation in SLC11A1 alters the risk for development of leishmaniasis66 and tuberculosis67 as well as autoimmune conditions such as juvenile rheumatoid arthritis68 and type 1 diabetes69. Interestingly, HIF differentially binds and activates Z-DNA-forming microsatellite polymorphisms in the SLC11A1 promoter region, thereby shaping allele expression phenotypes70, a newly described function for a transcription factor. Through its differential interaction with variant SLC11A1 promoters, HIF transcriptional regulation has the potential to influence inheritable differences in infectious and inflammatory disease susceptibility within and between human populations71.

**HIF: a drug target to boost innate immunity**

Given the accumulating evidence that HIF functions as a ‘master regulator’ of the innate immune function of phagocytes72, it is possible that boosting HIF activity through pharmacological strategies might provide a new approach to aid the treatment of certain infectious disease conditions73. This concept is supported by the observation that macrophages that lack VHL and thus have constitutively high levels of HIF are markedly more efficient than wild-type macrophages at killing Gram-positive and Gram-negative bacteria in vitro74. This implies that normal phagocytic cells are not as adept at killing bacteria as they could be, mainly because their activation is tightly regulated to limit unnecessary inflammatory injury. However, the common clinical scenario of invasive bacterial infection is linked to a failure of innate immunity to control the infecting pathogen, and it is possible that such patients might benefit from augmentation of phagocytic cell bactericidal activity by HIF. As proof-of-principle, addition of a series of pharmacological agonists of HIF, each a hypoxia
mimetic” that restricts prolyl hydroxylase access to iron, directly enhanced mouse macrophage bacterial activity in vitro. Similarly, a dose-dependent enhancement of the bacterial activities of human whole blood, neutrophils and the macrophage cell line U937 against the pathogen *S. aureus* was achieved using one such hypoxia mimetic, L-mimosine. Local treatment with L-mimosine significantly delayed progression of *S. aureus* abscesses in a mouse subcutaneous challenge model.

HIF agonists that are designed to activate phagocyte bacterial mechanisms could conceivably be used alongside conventional antibiotics in localized infections, and would be predicted to function effectively against drug-resistant bacteria such as methicillin-resistant *S. aureus* (MRSA). The selective pressure for pathogens to evolve resistance to HIF agonist therapy may be negligible as the drug targets the host and not the pathogen, thereby deploying a multifaceted combination therapy of natural antimicrobial molecules. The effects of such drugs would not be restricted to immune cells. However, chronic administration of a prolyl hydroxylase inhibitor or HIF agonist to non-human primates was not associated with significant toxicity, and these compounds have advanced to Phase Ib–II clinical trials in over 700 patients for treatment of the anaemia associated with chronic kidney disease. An important cautionary note should be emphasized: based on evidence from studies of mice, HIF agonists are probably inappropriate for systemic therapy of patients that have disseminated infections and symptoms of sepsis, as macrophage pro-inflammatory cytokine and NO release could be rapidly increased and symptoms could worsen. Instead, one appealing starting point may be local or topical administration for treatment or prophylaxis of bacterial skin and wound infections, where fortification of the antimicrobial barrier provided by keratinocytes and myeloid cells could be coupled with the reported enhancement of cutaneous wound healing associated with HIF augmentation.

Finally, it is possible that strategies to inhibit HIF for the treatment of chronic inflammatory disorders, such as rheumatoid arthritis, may provide a safer therapeutic margin than cytotoxic agents and high-dose steroids, as post-translational regulation of HIF1α levels may allow rapid restoration of innate immune function of phagocytes following drug withdrawal in the event of opportunistic infection.

### Conclusions and future directions

A wealth of emerging information shows that HIF and the hypoxic response are deeply involved with the regulatory pathways of innate immune defence. The key implication of these findings is that the nature and magnitude of host bacterial and inflammatory activities are highly dependent on factors in the local tissue microenvironment — for example, oxygen tension and iron availability — and cannot be simply extrapolated from in vitro model systems under ambient conditions. Through HIF control of immune cell energetics and gene expression pathways, antimicrobial activities can be focused and amplified where they are needed most, namely foci of tissue infection, which are harsh and threatening microenvironments where oxygen and nutrients are limiting and cytotoxic molecules abound. We anticipate that future studies will reveal that important human pathogens modulate HIF activation pathways to subvert innate immunity or provoke dysregulated inflammation, contributing to key clinical manifestations. A detailed understanding of the relationships between HIF pathways of innate immune signal transduction such as TLR–NF-κB signalling and the deployment of various immune effector molecules will provide a clearer and more physiological understanding of infectious and inflammatory disease pathogenesis. Because of the short half-life and well-understood mechanism for post-translational regulation of HIF levels, HIF is an attractive pharmacological target to fine-tune immune cell functions for the treatment of human disease.
This article shows the potential link of HIF1 upregulated in activated macrophages to the atheromatous inflammatory plaque phenotype and the inflammatory aetiology of atherosclerosis. The bactericidal capacity of phagocytes is enhanced by HIF-1α-dependent NF-κB activation. HIF interacts with innate immunity receptors TLR2 and TLR6 during hypoxia. Neutrophils from patients with alpha-1-antitrypsin deficiency experience hypoxia-induced neutrophil degranulation. This paper indicates that HIF1α expression is associated with an inflammatory aetiology of atherosclerosis. hypoxia induces NF-κB activity in activated human T lymphocytes. The hydroxylase inhibitor 2,5-dihydroxybenzoic acid stabilizes RTA expression during hypoxia: latency breaking and its activation-inducible short isoform I.1 are required for its intracellular survival advantage. Stable association of the hypoxia-inducible factor-1 alpha (HIF-1α) 3′ untranslated region (UTR) with the microRNA-155 is critical to NF-κB activation in rhesus macaques. Activation of hypoxia-inducible factor-1 alpha (HIF-1α) is critical to NF-κB activation in rhesus macaques. Cutting edge: essential role of Siah1-mediated prolyl hydroxylase inhibition for its intracellular survival advantage. The hydroxylase inhibitor 2,5-dihydroxybenzoic acid stabilizes RTA expression during hypoxia: latency breaking and its activation-inducible short isoform I.1 are required for its intracellular survival advantage. α-2 integrin and LRP-5 interact to regulate innate immune responses. Cutting edge: hypoxia-inducible factor-1 facilitates early-stage invasive cervical cancer. Activation of hypoxia-inducible factor 1α (HIF-1α) by enterobacteriaceae and their siderophores. Activation of hypoxia-inducible factor 1α (HIF-1α) 3′ untranslated region (UTR) with the microRNA-155 is critical to NF-κB activation in rhesus macaques.
