*Trichomonas vaginalis* - Inflammasomes - Pyroptosis

**Abstract**

*Trichomonas vaginalis* is a sexually transmitted, eukaryotic parasite that causes trichomoniasis, the most common nonviral, sexually transmitted disease in the USA and worldwide. Little is known about the molecular mechanisms involved in the host immune response to this widespread parasite. Here we report that *T. vaginalis* induces NLRP3 inflammasome activation in human macrophages, leading to caspase-1 activation and the processing of pro-IL-1β to the mature and bioactive form of the cytokine. Using inhibitor-based approaches, we show that NLRP3 activation by *T. vaginalis* involves host cell detection of extracellular ATP via P2X7 receptors and potassium efflux. In addition, our data reveal that *T. vaginalis* inflammasome activation induces macrophage inflammatory cell death by pyroptosis, known to occur via caspase-1 cleavage of the gasdermin D protein, which assembles to form pores in the host cell membrane. We found that *T. vaginalis*-induced cytolysis of macrophages is attenuated in gasdermin D knockout cells. Lastly, in a murine challenge model, we detected IL-1β production in vaginal fluids in response to *T. vaginalis* infection in vivo. Together, our findings mechanistically dissect how *T. vaginalis* contributes to the production of the proinflammatory IL-1β cytokine and uncover pyroptosis as a mechanism by which the parasite can trigger host macrophage cell death.

**Introduction**

*Trichomonas vaginalis* is a eukaryotic parasite that infects the urogenital tract of women and men. The parasite is transmitted through sexual intercourse and, after having colonized its human host, causes the disease trichomoniasis, which is the most common nonviral, sexually transmitted infection (STI) in the USA [1] and worldwide [2]. While *T. vaginalis* STI can be asymptomatic in many individuals [3], others experience inflammation of the vagina, cervix, or prostate [4]. The inflammatory response mounted against the parasite is predicted to fuel multiple...
adverse health effects associated with *T. vaginalis* infection. These include a higher incidence of premature births [5], an increased risk of cervical [6, 7] or aggressive prostate cancer [8, 9], and an increased risk of acquiring [10] and potentially transmitting the human immunodeficiency virus (HIV) to a sexual partner [11].

Despite the serious public health threat posed by *T. vaginalis*, limited knowledge exists regarding the molecular mechanisms by which *T. vaginalis* elicits inflammation. As an extracellular parasite, *T. vaginalis* survives in the human body via uptake of nutrients from host cells to which it can adhere and/or phagocytose and lyse, including vaginal or prostate epithelial cells [12], and red or white blood cells [13]. Currently, human clinical data regarding the specific innate immune response to *T. vaginalis* infections are scarce, and existing knowledge largely stems from human co-infection studies or from in vitro experiments. Cauci and Culhane [14] reported a significant increase in vaginal IL-1β levels in pregnant women who had bacterial vaginosis and a *T. vaginalis* coinfection compared to pregnant women with only bacterial vaginosis. Indeed, inflammatory profiling of human monocytes and monocyte-derived macrophages in response to *T. vaginalis* infection identified IL-1β as an upregulated cytokine [15–17]. However, the cellular mechanisms and requirements for the production of this important immune response factor during macrophage and *T. vaginalis* encounters are unknown. Here we delineate the cellular pathway that is activated in macrophages by *T. vaginalis* leading to the maturation and release of IL-1β.

Inflammasomes are multimeric cytosolic complexes that sense the presence of pathogens or changes in cellular homeostasis and activate commensurate innate immune responses. The inflammasome complex is defined by the responding sensor protein, which has characteristic structural domains and includes the nucleotide-binding oligomerization domain-like receptors (NLRs) NLRP1, NLRP3, and NLRC4, as well as the AIM2 and pyrin proteins [18]. Inflammasome assembly is initiated by NLR recognition of pathogen-associated molecular patterns (PAMPs) or endogenous danger-associated molecular patterns (DAMPS) [18]. Upon detecting these stimuli, the sensor proteins oligomerize and associate with the adaptor protein ASC in a multiprotein complex that recruits pro-caspase-1 and promotes its autoproteolytic processing [19, 20]. Mature protease caspase-1 then cleaves the pro-forms of inflammatory cytokines IL-1β and IL-18 to generate the mature bioactive forms capable of binding their cognate receptors and initiating cell signaling [21–27]. Two major outcomes of inflammasome activation are processing and release of mature IL-1β and induction of a rapid cell death termed pyroptosis [28, 29].

In this study, we show that *T. vaginalis* activates NLRP3 inflammasomes in human macrophages, leading to bioactive IL-1β production and pyroptotic cell death. The parasite-driven NLRP3 inflammasome activation involves sensing of ATP as a DAMP and potassium efflux, and IL-1β release in response to *T. vaginalis* can be detected in vivo in a mouse vaginal challenge study. Thus, *T. vaginalis* activation of NLRP3 inflammasomes leads not only to a strong macrophage proinflammatory response against the parasite, consistent with recent findings in prostate epithelial cells [30], but also to elimination of the macrophages in the process. The balance of innate immune detection and inflammatory response is likely to influence *T. vaginalis* colonization and pathogenesis differentially depending on the magnitude and stage of infection.

### Materials and Methods

#### Growth of Cells and Culture

*T. vaginalis* strains RV393 (New York, NY, USA; ATCC 50142 [31]) and MSA1132 (Mt. Dora, FL, USA [12]) were both obtained from Patricia Johnson’s Laboratory at UCLA. Parasites were treated with 50 μg/mL chloramphenicol and 5 μg/mL tetracycline for 6 days and then frozen down as stocks. The parasites were thawed from these stocks and passed daily for less than 2 weeks, as previously described [32]. In the continued presence of chloramphenicol and tetracycline. Human THP-1 monocytes (ATCC TIB-202) were cultured in RPMI medium supplemented with 10% fetal bovine serum (FBS), 0.05 mM 2-mercaptoethanol, 0.2% D-glucose, 10 mM HEPES, and 1 mM sodium pyruvate. The THP-1 monocytes were differentiated to macrophages by treating the cells with 25 nM PMA (phorbol 12-myristate 13-acetate; Thermo Fisher Scientific) for 24 h.

#### THP-1 Cas9 Cell Line

A Cas9 stable cell line was generated by transducing THP-1 cells with Lenti-Cas9-Blast lentivirus (Addgene 52962-LV). Spincfection was performed by spinning down THP-1 cells with viral particles supplemented with 10 μg/mL polybrene at 1,000 g, 32°C, for 1 h. After 48 h, cells were selected for stable expression of *Streptococcus pyogenes* Cas9 using blasticidin (10 μg/mL). Ten days after selection, the cells were harvested and Cas9 expression was confirmed by immunoblotting and qPCR.

#### Cloning of GSDMD sgRNAs

Two sgRNA sequences previously shown to successfully target the gasdermin D (GSDMD) gene were cloned into the lentiGuidePuro vector (Addgene; Plasmid #52963) as described previously [33]. The sgRNA sequences were as follows: GSDMD KO1 5′-TGAATGCTGGACCTTAAACC-3′ [from 34] and GSDMD KO2 5′-CTTGGTTTAGAGGTGGACCG-3′ [from 33; GeCKOv2 Library, identifier #HGLibA_20413].
GSDMD Knockout Cell Lines

Lentivirus was packaged in HEK 293T cells (ATCC CRL-3216) using the Fugene HD transfection reagent (Promega) and 4 μg of the gasdermin D sgRNA-lentiGuide-Puro construct, 4 μg of the packaging plasmid psPAX2 (Addgene; Plasmid #12260), and 4 μg of the VSV-G envelope expressing plasmid pMD2-G (Addgene; Plasmid #12259). THP-1 Cas9 cells (described above) were spin-infected with 10 μg/mL polybrene and viral particles for 1 h at 1,000 g, 32 °C. After 48 h, cells were selected for stable expression of the sgRNAs using puromycin (1 μg/mL). After 10 days of selection, the cell supernatants were removed and the cells lysed with lysis buffer. Caspase-1 activity was assessed per the manufacturer’s instructions.

T. vaginalis Co-Culture Experiments

A total of 1 × 10^6 THP-1 cells were seeded and differentiated in 96-well plates. T. vaginalis RU393 parasites were spun down at 2,061 g, washed once, and then resuspended in RPMI + 2% heat-inactivated FBS. Serial dilutions were performed to attain the desired T. vaginalis-to-macrophage ratios. Medium was aspirated from the THP-1 macrophages and 100 μL of T. vaginalis cell suspension was added to each well for inhibitor or chemical treatment experiments. Parasites were premixed with the vehicle or test compound and then added to the macrophages.

Cytokine and Caspase-1 Protein Analysis

IL-1β cytokine levels and caspase-1 protein levels present in cell culture supernatants were quantified using the DuoSet IL-1β ELISA kit and the Quantikine Human Caspase-1/ICE ELISA Kit (both from R&D Systems).

IL-1β Signaling Assay

HEK-Blue™ IL-1β Cells (InvivoGen) were purchased and grown in the company’s specifications. A total of 50,000 IL-1β Sensor Cells were seeded per well of a 96-well plate; 50 μL of cell supernatant from each experimental sample or a recombinant human IL-1β (InvivoGen) dilution was added to the IL-1β Sensor Cells and incubated at 37 °C, 5% CO₂, for 18 h. Secreted alkaline phosphatase activity was assessed by adding 50 μL of the HEK-Blue IL-1β reporter cell supernatants onto 150 μL of QUANTI-Blue™ Filter Reagent (InvivoGen) and measuring the optical density at 620 nm using an EnSpire Plate Reader (PerkinElmer). Background levels from THP-1 only or THP-1 cells treated with vehicle were subtracted from all values to report IL-1β signaling levels above background levels.

Caspase-1 Activity Assay

Caspase-1 activity assay was assessed using the Caspase-1/ICE Colorimetric Assay Kit (BioVision). A total of 2 × 10^6 THP-1 macrophages were seeded and differentiated in 6-well plates. T. vaginalis RU393 parasites were spun down at 2,061 g, washed once, and resuspended in RPMI + 2% heat-inactivated FBS; 1.5 mL of parasite suspension were added to each well. After a 2.5-h co-incubation, the cell supernatants were removed and the cells lysed with cell lysis buffer. Caspase-1 activity was assessed per the manufacturer’s specifications in whole cell lysates normalized by equal protein amounts.
cell lysates of THP-1 macrophages exposed to *T. vaginalis* for 4 h at an MOI of 1. Full-length pro-IL-1β (31 kDa) could be detected in both samples. Actin loading control and molecular weight markers in kilodalton are also shown. THP-1 macrophages were exposed to *T. vaginalis* for 2.5 h. The amount of caspase-1 activity was assayed by measuring cleavage of the p-nitroanilide-labeled YVAD peptide (YVAD-pNA) spectrophotometrically. The fold change relative to THP-1 cells alone is shown. Amounts of caspase-1 protein released into cell supernatants as quantified by ELISA. f, g THP-1 cells were co-incubated with *T. vaginalis* in the presence of the caspase-1 peptide inhibitor Ac-YCSD-CMK or vehicle control. Levels of bioactive IL-1β were detected using the IL-1β reporter cells (f) and IL-1β protein levels were detected by ELISA (g). For each experiment, samples were assayed at least in triplicate. Representative results from 2 (d, e) or 3 (a–c, f, g) independent experiments are shown. The graphs show the mean with standard deviations. *p < 0.05, **p < 0.01, compared to THP-1 cells (a, b, e) or vehicle treatment at that MOI (f, g).

**Results**

*T. vaginalis* Stimulates Bioactive IL-1β Secretion in a Caspase-1-Dependent Manner

The NLRP3 inflammasome is highly expressed and best characterized in cells of the myeloid cell lineage in-
including macrophages and dendritic cells [35, 36]. As macrophages are among the most abundant immune effector cells in the female reproductive tract [37], we investigated whether *T. vaginalis* activates NLRP3 inflammasomes in human macrophages. For our studies, we used the human THP-1 monocyte-like cell line, which is differentiated to macrophages using PMA treatment. NLRP3 inflammasome activation involves two signals. Signal 1, known as the priming step, occurs after receptor engagement, and signal transduction leads to NF-κB activation, which in turn stimulates increased transcription of the genes encoding pro-IL-1β and NLRP3 [38–40]. Signal 2, the activation step, is initiated by diverse microbial PAMPs and host cell DAMPs which lead to the physical assembly of the NLRP3 inflammasome complex. Examples of NLRP3 signal 2 activators include bacterial surface proteins, microbial pore-forming toxins, and viral RNA, as well as host cell DAMPs such as extracellular ATP, amyloid-β, and monosodium urate crystals [41, 42].

We found a dose-dependent increase in IL-1β secretion from THP-1 macrophages at increasing multiplicities of infection (MOIs) of *T. vaginalis* (Fig. 1a); LPS and ATP, two well-described NLRP3 inflammasome inducers that provide signal 1 and signal 2, respectively [43], served as positive controls. While IL-1β protein has been detected by ELISA in the monocyte/macrophage cytokine response to *T. vaginalis* exposure [15–17], it was unclear if this represented the pro-form of IL-1β released secondary to parasite-induced cell lysis or whether it was the processed and bioactive form of the inflammatory cytokine. To test the bioactivity of IL-1β generated upon THP-1 macrophage exposure to *T. vaginalis*, we added cell supernatants from the co-culture experiments to HEK-Blue IL-1β Sensor Cells (InvivoGen). These reporter cells express IL-1R (IL-1 receptor) to initiate cell signaling and trigger the production of a SEAP reporter enzyme that can convert a colorimetric substrate to provide a readout for IL-1β signaling. With recombinant bioactive IL-1β serving as a positive control for IL-1β signaling activity, Figure 1b shows that *T. vaginalis* co-incubation with THP-1 macrophages led to processing of pro-IL-1β and generation of bioactive IL-1β capable of IL-1R-mediated cell signaling. LPS and ATP served as positive controls for NLRP3 inflammasome activation in the THP-1 cells. The immunoblot analysis in Figure 1c confirms detection of the 17-kDa bioactive IL-1β cleavage product in whole cell lysates from THP-1 macrophages exposed to *T. vaginalis*, which was not detected in the uninfected control. Conversely, the full-length pro-IL-1β protein, which has a molecular weight of 31 kDa but migrates with an apparent molecular weight of ~36 kDa, was detected in both uninfected THP-1 macrophages and macrophages exposed to *T. vaginalis*. Therefore, macrophage co-incubation with *T. vaginalis* leads to active production of processed and bioactive IL-1β.

Canonical inflammasome assembly and activation leads to the autoproteolytic processing of the proenzyme form of caspase-1 (45 kDa) to its active form composed.

---

**Fig. 2. Trichomonas vaginalis** activates NLRP3 inflammasomes in THP-1 macrophages. THP-1 macrophages were exposed to *T. vaginalis* at a multiplicity of infection of 5 (*T. vaginalis*:host) for 4 h in the presence of CRID3 (a, b), an NLRP3/AIM2 inflammasome inhibitor, or exogenous KCl and NaCl (c, d). Levels of bioactive IL-1β were detected using the IL-1β reporter cells (a, c) and total IL-1β protein levels were detected by ELISA (b, d). A representative result from 3 independent experiments is shown. The graphs show the mean with standard deviations. *p < 0.05, **p < 0.01, compared to THP-1 cells co-incubated with *T. vaginalis* vehicle treatment.
of a heterodimeric tetramer of the p20 and p10 subunits [44]. To quantify caspase-1 activity, we assayed cleavage of the chromogenic peptide YVAD-pNA. After 2.5-h co-incubation with T. vaginalis, we detected a ~4-fold increase in caspase-1 activity from THP-1 cells at an MOI of 5 and a ~3-fold increase at an MOI of 1 (Fig. 1d). Caspase-1 can be released into cell supernatants after inflammasome activation [45], and we found a dose-dependent release of high amounts of caspase-1 in THP-1 supernatants following exposure to increasing MOIs of T. vaginalis [46] (Fig. 1e). Treatment with the specific Ac-YVAD-CMK peptide inhibitor of caspase-1 markedly ablated bioactive IL-1β production (Fig. 1f), a result corroborated when total IL-1β was quantified by ELISA (Fig. 1g). Together, these results indicate that upon exposure to T. vaginalis, caspase-1 activity is increased in THP-1 cells and leads to the processing of pro-IL-1β to bioactive IL-1β.

T. vaginalis Activates NLRP3 Inflammasomes

Multiple innate immune sensor proteins can be assembled to form different types of inflammasome complexes [18]. Many inflammasomes are activated by bacterial components such as LPS or flagellin [46] that are not found in the eukaryotic T. vaginalis parasite. NLRP3 inflammasomes were strong molecular candidates for the observed generation of bioactive IL-1β, since they can also be activated in response to host cell perturbations and by sensing DAMPs potentially released during cellular injury inflicted by T. vaginalis. To investigate the role of NLRP3 as the sensor protein driving IL-1β processing, we co-incubated T. vaginalis with THP-1 cells in the presence or absence of CRID3, which inhibits ASC oligomerization to block both NLRP3 and AIM2 inflammasomes [47]. CRID3 treatment completely ablated bioactive IL-1β signaling from THP-1 macrophages exposed to T. vaginalis at an MOI of 5 or 10 (Fig. 2a); similar reductions in total IL-1β detected by ELISA were observed at each MOI (Fig. 2b). A variety of ligands or cell perturbations can serve as upstream activators of NLRP3 inflammasome activation; however, the precise molecular mechanism shared by these various pathways to result in NLRP3 inflammasome activation is still a subject of active investigation. K+ efflux has been identified as a common signaling event in many cases of NLRP3 inflammasome activation [41, 48, 49]. Therefore, we compared the levels of IL-1β signaling in THP-1 cells co-incubated with T. vaginalis in the presence or absence of added extracellular KCl to counteract the effects of K+ efflux [49] and observed a dose-dependent inhibition of IL-1β signaling (Fig. 2c) and total IL-1β protein levels (Fig. 2d). As a control for addition of extracellular ions, exogenous addition of NaCl only slightly modified IL-1β signaling (Fig. 2c) and had no effect on IL-1β protein levels (Fig. 2d). Together these results indicate that T. vaginalis induction of IL-1β secretion in THP-1 macrophages is mediated through NLRP3 inflammasome activation in a scenario where K+ efflux is required.

ATP-P2X7 Receptor Signaling and Macrophage Contact Contributes to T. vaginalis-Induced Inflammasome Activation

Extracellular ATP serves as a DAMP by binding to cell surface P2X7 receptors that provoke K+ efflux from the cell and subsequent NLRP3 inflammasome activation [50–55]. To test whether ATP plays a role in inflammasome activation by T. vaginalis, we co-incubated the parasites with THP-1 macrophages in the presence of ox-A TP, which covalently and irreversibly binds to P2 family receptors (P2XR), inhibiting their ATP-mediated ion transport and ATP-dependent IL-1β release [54, 56]. oxATP treatment led to a dose-dependent reduction in IL-1β signaling and IL-1β protein levels in THP-1 macrophages exposed to T. vaginalis (Fig. 3a, b). To further probe P2X7 receptor involvement, we used glyburide (also known as glibenclamide), which inhibits P2X7 receptors and is also a broad-spectrum inhibitor of ATP-binding cassette transporters. As a result of blocking K+ efflux, glyburide inhibits NLRP3 inflammasomes [57]. Glyburide treatment completely ablated the production of bioactive IL-1β in T. vaginalis-infected THP-1 macrophages (Fig. 3c), and more than halved the amount of IL-1β protein detected by ELISA (Fig. 3d). Together, these results indicate that exposure of macrophages to T. vaginalis leads to inflammasome activation via P2X7 receptor-mediated K+ efflux in response to extracellular ATP.

To determine if direct contact between the parasite and the THP-1 cells was necessary to induce inflammasome activation, we placed a filter in between the macrophages and T. vaginalis, which allows soluble materials to pass through but prohibits direct contact between the parasites and the THP-1 macrophages. In conditions where T. vaginalis was placed above the filter (no direct contact), the secretion and processing of IL-1β were markedly reduced (Fig. 3e, f). Thus, physical contact of the host macrophages with the parasites is critical for sensing either an unknown PAMP on T. vaginalis or, more likely, a DAMP (e.g., ATP) arising from the host cell generated upon cell lysis that serves as a signal for inflammasome activation.
T. vaginalis Inflammasome Activation Leads to THP-1 Macrophage Cell Death by Pyroptosis

In addition to IL-1β secretion, NLRP3 inflammasome activation can lead to an inflammatory cell death called pyroptosis. Cell lysis occurs after the mature caspase-1 protease has cleaved the gaskermin D protein [28], which then oligomerizes [58] and forms pores in the plasma membrane [29], prompting cell swelling and membrane rupture. Pyroptosis is recognized as a distinct form of cell death in large part due to its fast nature (compared to apoptosis) and its accompanying “fiery” inflammatory response [59]. Pyroptosis is commonly detected by monitoring downstream membrane damage that leads to release of intracellular proteins like LDH. Of note, LDH assays have been the standard assay used by many investigators to monitor T. vaginalis lysis of vaginal epithelial cells and prostate epithelial cells [12]. To test how T. vaginalis-induced inflammasome activation may influence macrophage pyroptosis, we examined the effect of inflammasome inhibitors on macrophage LDH release following infection with the parasite. Co-incubation of cells in the presence the caspase-1 inhibitor Ac-YVAD-CMK led to a significant reduction in host cell lysis at each MOI (Fig. 4a). Similar reductions in THP-1 macrophage lysis by T. vaginalis were also obtained with the NLRP3/AIM2 inflammasome inhibitor CRID3 (Fig. 4b). A complete re-

Fig. 3. Response to extracellular ATP via P2X7 receptor signaling and physical contact contributes to Trichomonas vaginalis inflammasome activation. THP-1 macrophages were exposed to T. vaginalis at a multiplicity of infection (MOI) of 5 (T. vaginalis:host) for 4 h in the presence of oxidized ATP (oxATP; a, b) or glyburide (c, d), an ATP-gated P2X7 receptor inhibitor. e, f A 0.4-μm membrane filter that allowed soluble materials to flow through but prevented contact was placed in between THP-1 macrophages and T. vaginalis in the “above filter” condition, or parasites were placed below the filter to allow contact between T. vaginalis and macrophages (“contact” condition). THP-1 cells were treated with 10 ng/mL LPS + 5 mM ATP as a positive control for NLRP3 activation. Levels of bioactive IL-1β were detected using the IL-1β reporter cells (a, c, e) and total IL-1β protein levels were detected by ELISA (b, d, f). Representative results from 3 independent experiments are shown in a–d, and from 2 independent experiments in e and f. The graphs show the mean with standard deviations. a–d ** p < 0.01 compared to THP-1 cells exposed to T. vaginalis in the presence of vehicle control. e, f * p < 0.05, ** p < 0.01, compared to the contact with T. vaginalis condition at that MOI.
Inflammasome activation by *Trichomonas vaginalis* contributes to pyroptosis. Cytolysis of host cells was assessed by measuring lactate dehydrogenase (LDH) release from dying macrophages. **a**, **b** THP-1 macrophages were incubated with *T. vaginalis* using different multiplicities of infection (MOIs; *T. vaginalis*:host cell) for 4 h in the presence of vehicle, the caspase-1 peptide inhibitor Ac-YVAD-CMK (**a**), or the NLRP3/AIM2 inhibitor CRID3 (**b**). The data are representative from 3 experiments. The graphs show the mean with standard deviations. *p < 0.05, **p < 0.01, compared to vehicle treatment at that MOI. **c**, **d** Gasdermin D (GSDMD) was knocked out in THP-1 cells using CRISPR-Cas9. **c** Confirmation of gasdermin D knockout (KO) in 2 clones by Western blot analysis using an anti-gasdermin D antibody. Actin loading control and molecular weight markers in kilodalton are also shown. **d** GSDMD KO cells or wild-type (WT) THP-1 cells were exposed to *T. vaginalis* at an MOI of 5 for 4 h. The average fold change in percent cytolysis compared to THP-1 WT cells from 3 independent experiments with standard errors of the mean are shown. **p < 0.01 compared to THP-1 WT cells.

As a pilot study to determine if activation of IL-1β release is observed in vivo, we modified a previously established mouse model of *T. vaginalis* infection [62]. Unfortunately, *T. vaginalis* mouse models have required estrogen treatment together with the synthetic glucocorticoid and immunosuppressant dexamethasone [63] prior to and after *T. vaginalis* infection in order to facilitate colonization by the parasite [62]. To investigate inflammasome activation by *T. vaginalis* under minimal immune suppression conditions, we inoculated mice with one of the most virulent clinical strains available, called MSA1132 [12], using an optimized protocol illustrated schematically in Figure 5a. *T. vaginalis* strain MSA1132 also yielded bioactive IL-1β production in our in vitro studies (data not shown). Three days after parasite or mock (PBS) infection, we collected vaginal lavages and examined IL-1β protein levels by ELISA. *T. vaginalis* infection led to a statistically significant increase in IL-1β secretion in vivo (Fig. 5b), consistent with our in vitro results.

**Discussion**

In this work we show that upon contact with THP-1 human macrophages, *T. vaginalis* can activate NLRP3 inflammasomes, lead to release of bioactive IL-1β, and induce pyroptotic cell death. We thus infer that direct contact of *T. vaginalis* with macrophages is necessary to deliver both signals required for NLRP3 inflammasome activation. Inflammasome activation by *T. vaginalis* is mediated in part by sensing extracellular ATP via P2X7 receptors, which lead to K+ efflux. Midlej and Benchimol [64] have shown that *T. vaginalis* inflicts membrane damage upon host cell contact, a likely requisite for the release of ATP and other DAMPs that can serve as signal 2 for inflammasome activation. 100 μM oxATP can inhibit the ability of 5 mM ATP to stimulate macrophage IL-1β production [65]. Similarly, we observed inhibition of IL-1β.
signaling with 100 μM oxATP, but higher doses of oxATP yielded still greater inhibition, so it is likely that significant ATP quantities are generated locally by T. vaginalis-induced cell damage allowing macrophage P2X7 receptor activation. We hypothesize that the general mechanism of host cell injury by T. vaginalis and subsequent release of DAMPs may underpin our preliminary observation of T. vaginalis-induced IL-1β secretion in our murine short-term challenge model.

Several groups have reported T. vaginalis activation of NF-κB in vaginal epithelial cells, human monocytic-derived macrophages, murine macrophages, and THP-1 macrophages [16, 17, 66, 67], establishing a precedence for the parasite’s ability to provide a signal 1 required for NLRP3 inflammasome priming. To date, the only T. vaginalis cell surface component shown to contribute to NF-κB activation is the parasite’s glycocalyx [68], now known as Tv lipoglycan [69]. Toll-like receptor (TLR) 2 contributes to sensing of T. vaginalis by murine macrophages leading to NF-κB signaling [67]. It remains to be mechanistically investigated what other TLRs contribute to sensing T. vaginalis. TLR4 involvement has been implicated by indirect evidence, as cervicovaginal lavages from T. vaginalis-infected women stimulated TNF-α production from TLR4-responsive murine splenocytes at higher levels than splenocytes nonresponsive to TLR4 ligands [70]. In HeLa cells, TLR2, TLR4, and TLR9 expression is increased upon infection with T. vaginalis [71], and TLR4 upregulation has also been reported in a prostate stromal cell line exposed to the parasite [72]. Further dissection of how T. vaginalis contact with human macrophages leads to the generation and delivery of both signal 1 and signal 2 is a subject of ongoing investigation in our laboratory.

Our work has also demonstrated that T. vaginalis activation of the NLRP3 inflammasome in macrophages contributes to their physical lysis via pyroptosis, the first direct demonstration that the parasite can kill host cells through this inflammatory cell death pathway. Gu et al. [30] found that T. vaginalis can activate NLRP3 inflammasomes in a prostate epithelial cell line, but measures of cell viability, pyroptosis, or gasdermin D involvement were not reported. Nevertheless, our results and that of Gu et al. [30] add T. vaginalis to the growing number of sexually-transmitted pathogens that lead to inflamma-

T. vaginalis Activates NLRP3 Inflammasomes and Induces Pyroptosis
innate immunity and the shaping of adaptive immunity [78, 79]. These functions include inducing fever, promoting increased leukocyte recruitment to the infection site, and enhancing effector functions and cell survival [78]. Increased neutrophil numbers are reported in vaginal lavages of T. vaginalis-infected women [14, 80], but it remains unknown whether in human infections the increased leukocyte recruitment contributes to controlling the infection or to inducing pathology. An example of the latter adverse effects occurs with the extracellular fungus Candida albicans, in which NLRP3 inflammasome activation contributes to pathogenesis by promoting increased neutrophil influx and vaginitis in a murine model of infection [81, 82].

The physical lysis of host macrophages through pyroptosis likely mitigates the magnitude of the host innate immune response to T. vaginalis. For example, although we detected increased IL-1β production upon T. vaginalis infection in our murine infection model, we did not observe any gross visible phenotypes. Similarly, a majority of infected individuals are also asymptomatic [3]. This dichotomy highlights the complexity in the biology of T. vaginalis infections, in which inflammasome activation occurs in response to the parasite; however, the lysis of IL-1β-producing cells by the parasite may affect the amounts and effects of the bioactive IL-1β produced. The parasite is also highly motile with 5 flagella [83, 84]. This property likely influences how long the parasite remains in contact with host cells to allow for parasite sensing, how effective released host effector molecules are at targeting the parasite, and the effect of recruited leukocytes, if the parasite can physically swim away. Other parasite virulence factors also help dampen the local immune response – and potentially the effects of inflammasome activation on adaptive immunity. For example, T. vaginalis proteases can degrade complement components and antibodies [85], and the parasite can also lyse B cells and T cells [15]. T. vaginalis also expresses ectoATPases which can degrade extracellular ATP [86], the latter of which we identified to serve as a DAMP for NLRP3 inflammasome activation. Future work testing the effect of parasite mutants and uncovering such parasite virulence factors will allow us to broaden our understanding of the overall innate immune response, of its impact on T. vaginalis survival in the host, and of the observation that T. vaginalis frequently causes persistent and recurrent infections [87].

It is well recognized that the immune response to T. vaginalis is complex and that the outcomes of infection vary [3, 88]. The potency of inflammasome activation and differential macrophage lysis through pyroptosis by different strains may contribute to the observed differences in host responses. Our work has identified ATP sensing and K+ efflux as activators of NLRP3 inflammasomes in macrophages responding to T. vaginalis infection. These general processes are likely to be elicited in other cell types, such as the vaginal and cervical cells first encountered by the parasite and immune cells recruited to the infection site. Our work has set the foundation for further investigation into how T. vaginalis activates inflammasomes and how this molecular pathway contributes to IL-1β-mediated immune responses and proinflammatory host cell death.

Acknowledgements

We would like to thank Joshua Olson and the University of California, San Diego (UCSD) vivarium staff for help with the establishment of our animal protocol and animal experiments. We would also like to thank Dr. Patricia J. Johnson for providing T. vaginalis strains and for helpful discussion of the manuscript.

Statement of Ethics

The animal work was approved by and conducted in accordance with the UCSD Institutional Animal Care and Use Committee (IACUC), protocol No. S00227M. UCSD is accredited by the American Association for Accreditation of Laboratory Animal Care (AAALAC).

Disclosure Statement

The authors have no conflicts of interest to declare.

Funding Sources

A.M.R. was supported by the UC President’s Postdoctoral Fellowship and the San Diego IRACDA Fellowship (NIH/NIGMS K12 GM06852). K.A.P. was supported by the UC Chancellor’s Postdoctoral Fellowship. Research was supported by NIH grants HD090259 and GM114139 (V.N.).

Author Contributions

Inflammasomes and Induces Pyroptosis

T. vaginalis
